

Experimental Physics Vb (WS 2023/2024)

Exercise 7

Tutorial: 1

Deadline: 21.01.2025

Task 1: The sun as a neutron star

(a) *neutron star*

$$M_{\text{sun}} = M_n = \rho \frac{4}{3} \pi R_n^3$$

$$R_n = \left(\frac{3M_{\text{sun}}}{4\pi\rho} \right)^{\frac{1}{3}} = 9.83 \text{ km}$$

(b) *rotation*

The moment of inertia of an infinitesimal mass element is given by $dI = dm r^2$, where r is the distance from the axis of rotation. Since this relationship holds for each infinitesimal element, the total moment of inertia, obtained by summing or integrating over all such elements, retains the same proportionality:

$$I = \int dI \propto MR^2$$

With M as the total mass and R as same characteristic length. In the case of a spherical body one can therefore write the moment of inertia as $I = \lambda MR^2$, where λ denotes a constant value characteristic for the inertia of a sphere.

During the collapse of the star, angular momentum has been conserved, from that follows:

$$L_n = L_{\text{sun}}$$

$$\lambda M_n R_n^2 \omega_n = \lambda M_s R_s^2 \omega_s$$

1.1

$$\omega_n = \omega_s \frac{R_s^2}{R_n^2} = 13504 \text{ s}^{-1}$$

(c) *stability*

The neutron star would shed its outer layers if the centrifugal force is greater than the gravitational one:

$$a_Z > a_G$$

$$\begin{aligned}\frac{v^2}{r} &> \frac{GM}{r^2} \\ \omega^2 r &> \frac{GM}{r^2} \\ 1 &> \frac{GM}{r^3 \omega^2} = 0.767\end{aligned}$$

That is to say, the neutron star would be *unstable*.

Task 2: Solar constant

(a) *average radiant power*

Note that θ will only be integrated from 0 to $\pi/2$, which corresponds to the fact, that only half of the earth's surface is illuminated at any given time. 2.1

$$\begin{aligned}\bar{P}_{\text{earth}} &= \frac{P_{\text{total}}}{A} \\ &= \frac{1}{4\pi R^2} \int dS \hat{n} \cdot \vec{P} \\ &= \frac{1}{4\pi R^2} \int dS \begin{pmatrix} \sin \theta \cos \phi \\ \sin \theta \sin \phi \\ \cos \theta \end{pmatrix} \cdot \begin{pmatrix} 0 \\ 0 \\ P \end{pmatrix} \\ &= \frac{1}{4\pi R^2} P \int dS \cos \theta \\ &= \frac{1}{4\pi R^2} P R^2 \underbrace{\int_0^{\pi/2} d\theta \sin \theta \cos \theta}_{1/2} \underbrace{\int_0^{2\pi} d\phi}_{2\pi}\end{aligned}$$

$$\bar{P}_{\text{earth}} = \frac{P}{4} = 342 \frac{\text{W}}{\text{m}^2}$$

2.2

The task specifically asks for the radiant power on the Earth's surface, i.e. not just at the "upper edge" of the atmosphere, but I'm going to ignore that.

(b) *mass loss*

$$\dot{m} = \frac{P_{\text{sun}}}{c^2} = \frac{4\pi d_{\text{sun/earth}}^2 P}{c^2} = 4.14 \cdot 10^9 \frac{\text{kg}}{\text{s}}$$

(c) *neutrino flux*

For light stars like the sun almost all energy comes from the pp-cycle, the net reaction being:

Where the 26.73 MeV includes the energy that will be released, once the positrons annihilate with their antiparticle. Assuming further that the released energy is equal to the energy radiated away electromagnetically, the total neutrino flux is given by:

3.1

$$P_\nu = \frac{P}{26.73 \text{ MeV}/2} = 6.39 \cdot 10^{14} \frac{1}{\text{m}^2 \text{s}} = 6.39 \cdot 10^{10} \frac{1}{\text{cm}^2 \text{s}}$$

According to lecture 14 the expected neutrino flux due to the pp-cycle is $5.99 \cdot 10^{10} \frac{1}{\text{cm}^2 \text{s}}$ with the total neutrino flux being approximately $6.5 \cdot 10^{10} \frac{1}{\text{cm}^2 \text{s}}$. The calculated neutrino flux aligns nicely with these numbers.

Task 3: Apparent magnitude

$$m = -2.5 \cdot \log_{10} \frac{S}{S_0}, \quad S_0 = 2.518 \cdot 10^{-8} \frac{\text{W}}{\text{m}^2}$$

(a) *sun*

$$m_{\text{sun}} = -2.5 \cdot \log_{10} \frac{4\pi R_{\text{sun/earth}}^2 P}{S_0} = -85.4$$

3.2

(b) *distant vega*

The luminosity of Vega is $L = 47.2 L_\odot = 47.2 \cdot 3.828 \cdot 10^{26} \text{ W}$, and the distance to andromeda is $d = 0.78 \text{ Mpc} = 3.0857 \cdot 10^{22} \text{ m}$.

$$m_{\text{distant vega}} = -2.5 \cdot \log_{10} \frac{\frac{L}{4\pi d^2}}{S_0} = 29.2$$

3.3

Task 4: GZK cutoff

Using Wien's law the energy of the MBR is:

$$\lambda_{\text{max}} = 2898 \frac{\mu\text{m}}{\text{K}} \cdot 2.7 \text{ K}$$

$$E_\gamma = \omega \hbar = \frac{hc}{\lambda_{\text{max}}} = 158 \mu\text{eV}$$

The minimum energy of the proton is then given by:

$$m_{\Delta^+}^2 = s = (p_p + p_\gamma)^2$$

$$= (E_p + E_\gamma)^2 - (\vec{p}_p + \vec{p}_\gamma)^2$$

$$\begin{aligned}
&= E_p^2 + 2E_p E_\gamma + E_\gamma^2 - \vec{p}_p^2 - 2\vec{p}_p \vec{p}_\gamma - \vec{p}_\gamma^2 \\
&= m_p^2 + 2E_p E_\gamma + 2\sqrt{E_p^2 - m_p^2} E_\gamma \\
E_p^2 - m_p^2 &= \left(\frac{m_{\Delta^+}^2 - m_p^2}{2E_\gamma} - E_p \right)^2 \\
-m_p^2 &= \left(\frac{m_{\Delta^+}^2 - m_p^2}{2E_\gamma} \right)^2 - \frac{E_p}{E_\gamma} (m_{\Delta^+}^2 - m_p^2) \\
\boxed{E_p = E_\gamma \left(\frac{m_p^2}{m_{\Delta^+}^2 - m_p^2} + \frac{m_{\Delta^+}^2 - m_p^2}{4E_\gamma^2} \right) = 1.01 \cdot 10^{21} \text{ eV}}
\end{aligned}$$

4.1

4.2

Index of comments

- 1.1 The calculation is correct but not the final value, you're off by factor ~ 2
- 2.1 That's true but you still have to average so you need to take the full surface
- 2.2 Despite the above you got the correct answer
- 3.1 You didn't justify why you can assume that neutrinos carry away a negligible portion of the released energy
- 3.2 You need to take the solar constant (without propagating to Earth)
- 3.3 Should be 25 so you're a bit off, presumably from the 4π
- 4.1 A few things went wrong here:
 - The photon energy should be $\sim 656 \text{ meV}$ so you missed a factor in the conversion
 - The cutoff is actually lower because the Δ can be produced virtually. So the threshold energy is the sum of the proton and pion masses.Otherwise the calculation is correct
- 4.2
 - 1: $2+1+2$
 - 2: $1+3+2$
 - 3: $0+2$
 - 4: 3
